

# MIXTURE-OF-DIFFUSERS: DUAL-STAGE DIFFUSION MODEL FOR IMPROVED TIME SERIES GENERATION

**Anonymous authors**

Paper under double-blind review

## ABSTRACT

Synthetic Time Series Generation (TSG) is a crucial task for data augmentation and various downstream applications. While TSG has advanced, its effectiveness often relies on the availability of extensive training datasets, posing challenges in data-scarce scenarios. Generative Adversarial Networks (GANs) and Variational Autoencoders (VAEs) have shown promise, but they frequently struggle to capture the complex temporal dynamics and interdependencies inherent in time series data. To address these limitations, we propose a novel generative framework, Mixture-of-Diffusers (MoD). This approach decomposes the diffusion process into a collection of specialized diffusers, each designed to model specific patterns at distinct noise levels. Early-stage diffusers focus on capturing overarching global and coarse patterns, while late-stage diffusers specialize in capturing fine-grained details as the noise level diminishes. This decomposition empowers MoD to learn robust representations and generate realistic time series samples. The model is trained using a combination of multi-objective loss functions, ensuring both temporal consistency and alignment with the true data distribution. Extensive experiments on a diverse range of real-world and simulated time series datasets demonstrate the superior performance of MoD compared to state-of-the-art TSG generative models. Furthermore, rigorous evaluations incorporating both qualitative and quantitative metrics, coupled with assessments of downstream task performance on long-term generation and scarce time series data (see Figure 1), collectively validate the efficacy of our proposed approach.

## 1 INTRODUCTION

Synthetic time series generation (TSG) has become a focal point in recent research, driven by the growing demand for synthetic data in diverse applications, including data augmentation, anomaly detection, privacy preservation, and domain adaptation (Nikitin et al. (2024)). The ability to generate realistic time series data is crucial for augmenting machine learning models, especially when real-world data is limited, sensitive, or difficult to collect (Yoon et al. (2019b)). A primary objective of TSG is to create synthetic data that closely resemble real-world time series, preserving essential temporal dependencies and multidimensional correlations. This requires accurately capturing the intricate statistical properties and dynamics inherent in time series data, a challenging task due to their sequential and often stochastic nature (Qiu et al. (2018)).

Moreover, the scarcity of data, particularly in scenarios involving rare or unique events, hinders the training of generative models that rely on extensive datasets to capture the full nuances of the data distribution (Rubanova et al. (2019)). To address these challenges, various methodologies have been explored, leveraging various generative techniques such as GANs (Goodfellow et al. (2014)), VAEs (vae), and Diffusion Models. In early stage, GAN-based approaches have demonstrated proficiency in modeling complex, high-dimensional data distributions and capturing intricate time series characteristics. Models like TimeGAN (Yoon et al. (2019a)) and RCGAN (Esteban et al. (2017)) incorporate recurrent architectures within the GAN framework to effectively capture temporal dependencies. TimeGAN, for instance, combines an autoregressive model with adversarial training to generate realistic time series data that preserve temporal dynamics and feature correlations. However, GANs often suffer from training instability and issues such as mode collapse, limiting sample diversity and the ability to generate high-fidelity data, particularly for long-sequence time series (Ramponi et al. (2019)).

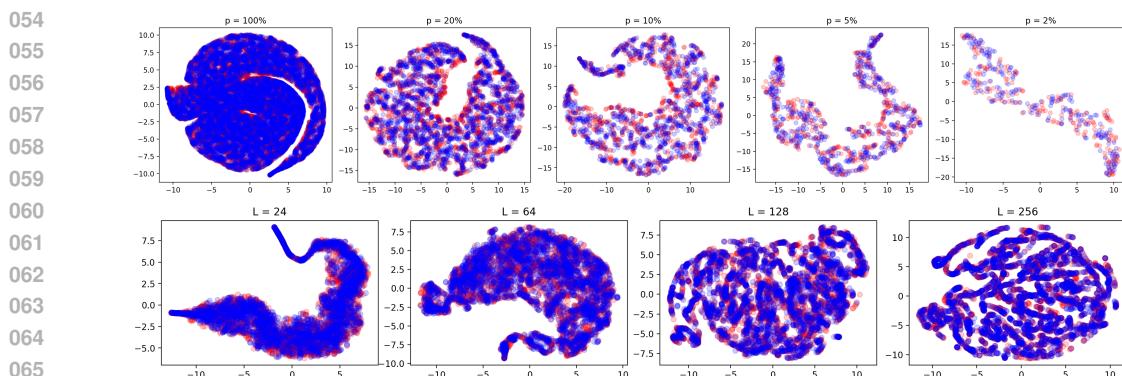

Figure 1: t-SNE visualization comparing synthetic data generated by our model (blue) to the original data (red). The upper panel demonstrates the model’s performance across varying proportions ( $p$ ) of the Sines dataset, ranging from 100% to 2%. The lower panel evaluates its effectiveness with different sequence lengths ( $L$ ) on the Energy dataset, from 24 to 256.

Later, VAEs have emerged as a leading technique in TSG due to their capacity to balance data fidelity with latent space statistical consistency. They encode input data into a latent space and then decode it back to reconstruct the original data, enabling the generation of new samples by sampling from the latent space. The Variational Recurrent Autoencoder (VRAE) (Fabius & van Amersfoort (2015)) extends the VAE framework to sequential data by incorporating recurrent neural networks into the encoder and decoder. However, VAEs typically strive for independent mapping between latent features and external conditions (vae). Nevertheless, these conditions often exhibit inter-correlations; changing one condition might unintentionally influence others, complicating the capture of accurate relationships among external conditions (Li et al. (2023)). Furthermore, VAEs are often challenged by the need to model complex temporal dynamics and may not efficiently handle the complexities of high-dimensional, long-sequence data (Alaa et al. (2022)).

Recently, in light of these challenges, diffusion-based models have emerged as a promising alternative (Dhariwal & Nichol (2021)). Originating from advances in computer vision and natural language processing, diffusion models involve a forward diffusion process where noise is incrementally added to the data, followed by a reverse process where a neural network is trained to reconstruct the data from the noisy input (Ho et al. (2020)). This framework effectively addresses core challenges faced by GANs and VAEs, such as training instability and mode collapse, by providing a stable learning process and effectively capturing the underlying data distribution (Lee et al. (2023)). Diffusion models have garnered significant attention due to their stable training and ability to model complex distributions. In the context of TSG, they offer several advantages, including the capability to model complex temporal dynamics and handle high-dimensional data with long sequences and variable lengths (Zhou et al. (2023a)). Approaches such as DiffWave (Kong et al. (2021)), Diffusion-TS (Yuan & Qiao (2024)), and TimeDiff (Shen & Kwok (2023)) have adopted the diffusion framework for modeling the data generation process. However, their application to long-term and scarce time series generation, remains an area that warrants further investigation.

To address these limitations, we investigate the application of diffusion models for TSG. Specifically, we propose a Mixture of Diffuser approach designed to learn the underlying representations and data distribution of multivariate time series data through a diffusion process, utilizing the trained denoiser model to generate new data samples that closely resemble the original data. Importantly, we segment the diffusion process into dual stages and employ a Transformer-based model at each stage to capture the dependencies and patterns corresponding to each stage. This approach enables each diffuser to concentrate on different aspects of the data that vary throughout the diffusion process. By doing so, the early-stage diffuser becomes specialized in capturing coarse-grained patterns in high-noise regimes, while the late-stage diffuser focuses on learning fine-grained patterns as the noise level decreases. The combination of representations learned by these two specialized diffusers empowers the model to learn the intricate dependencies and temporal dynamics inherent in time series data, facilitating the generation of highly realistic samples that closely resemble the original time series data. Our key contributions can be summarized as follows:

- We introduce a diffusion-based generative framework that partitions the diffusion process into two expert diffusers, each specialized in handling distinct noise levels, enabling the model to capture a wide range of temporal dynamics present in time series data.
- Our model segments the diffusion into two stages, allowing it to effectively discern overarching, coarse-scale patterns in the initial stage and intricate, fine-grained details in late stage, while facilitating a smooth transition between both. This stratified approach empowers the model to learn robust representations.
- To ensure the generation of both coherent and representative samples, we employ a joint training regimen that integrates different loss functions, concurrently enforcing temporal consistency and data distribution similarity.
- To underscore the model’s robustness and generalizability, we evaluate its performance on challenging time series data characterized by extended sequences and limited availability.

## 2 PROBLEM STATEMENT

This study introduces a diffusion-based generative approach designed to learn the underlying distribution of multivariate time series data, thereby producing synthetic samples that closely resemble real data. Let  $\{S_k \in \mathbb{R}^C\}_{k=1}^K$  represent a multivariate time series with,  $C$ , variables over,  $K$ , time steps. The time series data is segmented into sequences of length  $L$  to form the input  $x \in \mathbb{R}^{L \times C}$ . Given the data  $x$ , our objective is to train a diffusion model capable of generating samples that mimic the patterns observed in the original data. To achieve this, in the forward diffusion process, Gaussian noise  $\epsilon \sim \mathcal{N}(0, \mathbf{I})$  is gradually added over  $T$  diffusion steps. A neural network  $\epsilon_\theta(x)$  is then used to predict the noise at each diffusion step. By training  $\epsilon_\theta(x)$ , we aim to approximate the true data distribution  $q(x)$ , enabling the generation of high-quality synthetic time series data.

## 3 METHOD

As depicted in Figure 2, the proposed framework utilizes a Mixture-of-Diffusers (MoD) architecture to enhance the model’s capacity to capture diverse data patterns across different noise levels. The MoD comprises two transformer-based expert diffusers specifically designed to handle high and low noise levels, respectively. To incorporate valuable temporal context, the model leverages advanced positional encodings in conjunction with a Transformer encoder and Conv1D. The model is trained to minimize a loss function that combines MSE for noise prediction and KL divergence for posterior matching. The following sections provide a comprehensive analysis of each component.

### 3.1 DIFFUSION PROCESSES

Denoising Diffusion Probabilistic Models (DDPMs) are generative models that employ a two-stage process for data generation and reconstruction (Ho et al. (2020)). In the forward diffusion process, noise is gradually added to the input data,  $x_0$ , following a predefined noise schedule over  $T$  diffusion steps. At each step,  $t \in [1, T]$ , the diffused sample,  $x_t$ , is obtained by scaling the previous sample,  $x_{t-1}$ , with  $\sqrt{1 - \beta_t}$  and adding independent and identically distributed noise. This process can be mathematically represented as:

$$q(x_1, x_2, \dots, x_T | x_0) = \prod_{t=1}^T q(x_t | x_{t-1}); \quad (1)$$

$$q(x_t | x_{t-1}) = \mathcal{N}(x_t; \sqrt{1 - \beta_t} x_{t-1}, \beta_t I) \quad (2)$$

where  $\beta_t \in [0, 1]$  is the noise variance at step  $t$ . Based on Ho et al. (2020), we can leverage a forward diffusion process in Equation 2 to sample noisy data directly conditioned on the input  $x_0$ , where  $\alpha_t := 1 - \beta_t$ ,  $\bar{\alpha}_t := \prod_{i=1}^t \alpha_i$ , and  $\epsilon \sim \mathcal{N}(0, I)$ :

$$q(x_t | x_0) = \mathcal{N}(x_t; \sqrt{\bar{\alpha}_t} x_0, (1 - \bar{\alpha}_t) I) \quad (3)$$

$$x_t = \sqrt{\bar{\alpha}_t} x_0 + \sqrt{1 - \bar{\alpha}_t} \epsilon \quad (4)$$

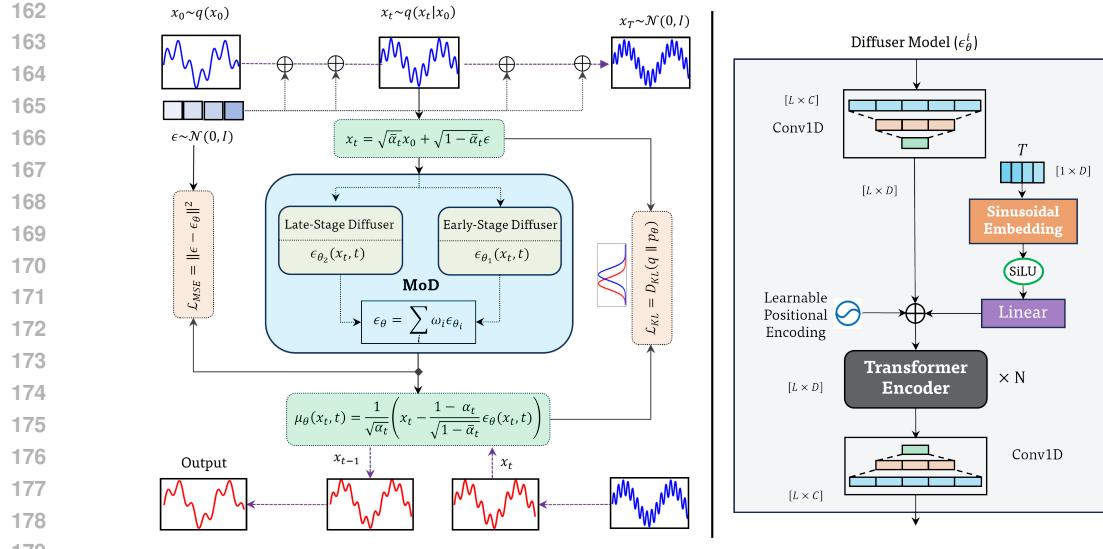

Figure 2: Schematic architecture of MoD. The left panel illustrates the core MoD component, along with the forward and reverse diffusion processes, where noise is progressively added and removed over ( $T$ ) timesteps. The right panel provides a detailed view of the Diffuser model’s architecture.

By applying Bayes’ theorem, we can derive the posterior distribution  $q(x_{t-1}|x_t, x_0)$  in terms of its mean  $\tilde{\mu}_t(x_t, x_0)$  and variance  $\tilde{\beta}_t$ :

$$\tilde{\mu}_t(x_t, x_0) = \frac{\sqrt{\bar{\alpha}_{t-1}\beta_t}}{1 - \bar{\alpha}_t} x_0 + \frac{\sqrt{\alpha_t(1 - \bar{\alpha}_{t-1})}}{1 - \bar{\alpha}_t} x_t; \quad \tilde{\beta}_t = \frac{1 - \bar{\alpha}_{t-1}}{1 - \bar{\alpha}_t} \beta_t \quad (5)$$

$$q(x_{t-1}|x_t, x_0) = \mathcal{N}(x_{t-1}; \tilde{\mu}_t(x_t, x_0), \tilde{\beta}_t I) \quad (6)$$

For sufficiently large  $T$  and a well-designed  $\beta_t$ ,  $x_t$  approaches an isotropic Gaussian distribution. While  $q(x_{t-1}|x_t)$  depends on the entire data distribution, we approximate it in the reverse diffusion process using our proposed MoD as follows:

$$p_{\theta}(x_{t-1}|x_t) = \mathcal{N}(x_{t-1}; \mu_{\theta}(x_t, t); \sigma_t^2 I) \quad (7)$$

We select to parametrize  $\mu_{\theta}(x_t, t)$  in the prior by directly predicting the noise component  $\epsilon_{\theta}$  in Equation 10 using the MoD, leveraging Equations 4 and 5 to derive:

$$\mu_{\theta}(x_t, t) = \frac{1}{\sqrt{\alpha_t}} \left( x_t - \frac{1 - \alpha_t}{\sqrt{1 - \bar{\alpha}_t}} \epsilon_{\theta}(x_t, t) \right) \quad (8)$$

$$x_{t-1} = \frac{1}{\sqrt{\alpha_t}} \left( x_t - \frac{1 - \alpha_t}{\sqrt{1 - \bar{\alpha}_t}} \epsilon_{\theta}(x_t, t) \right) + \sigma_t z \quad (9)$$

At each timestep, the MoD model predicts the noise component, and  $x_{t-1}$  is computed using Equation 9, where  $z \sim \mathcal{N}(0, I)$  when  $t > 1$  and 0 otherwise. The combination of two experts, guided by the weighting functions, enables the model to adaptively address varying noise levels during the denoising process.

### 3.2 MIXTURE OF DIFFUSERS (MoD)

Modeling the complex patterns and dependencies within multivariate time series data presents a significant challenge. While a single model may struggle to capture this full spectrum, the Mixture-of-Experts (MoE) framework offers a solution by allowing specialized models to handle specific data aspect, thereby augmenting the overall modeling capacity.

Time series data can be conceptualized as a signal comprised of information at multiple frequency scales. Low-frequency components, such as long-term trends, represent coarse-grained features that

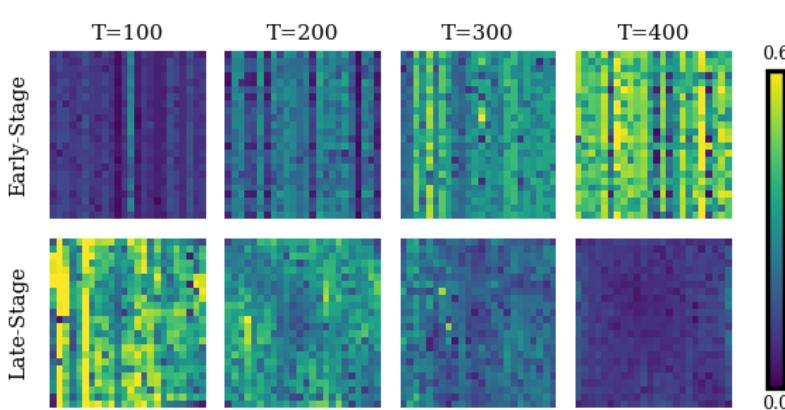

Figure 3: Attention weights heatmaps for encoder layer in both diffusers on ETTh dataset.

provide a foundational understanding of the data’s overall behavior. High-frequency components, on the other hand, capture fine-grained features like short-term patterns and fluctuations. In the context of time series diffusion, the forward diffusion process involves adding noise to the data, gradually disrupting its structure until it becomes indistinguishable from pure noise. This process increases the randomness in the data and affects both high-frequency and low-frequency components, making it more challenging to discern the original patterns. The reverse diffusion process, or denoising, can be viewed as dual-stage reconstruction process. In the early stages of the reverse diffusion process, characterized by high noise levels, fine-grained details are obscured. To establish a robust foundation for reconstruction, the model focuses on reconstructing the most prominent features that stand out despite the noise—often the coarse-grained, global structures and long-term trends. As the noise level decreases, finer details of the original data emerge. The model gradually refines the reconstruction by incorporating high-frequency details, such as short-term fluctuations.

Building upon this concept, our proposed MoD framework utilizes two specialized expert Diffusers, each learns specific underlying patterns within its designated domain of expertise under specific noise regime. This segmentation of the diffusion process into two distinct stages aligns perfectly with the idea that different patterns and characteristics within time series data become more prominent at various stages of the diffusion process, particularly as the noise level fluctuates:

- **Early-Stage Diffuser ( $\epsilon_{\theta_1}$ ):** Specializes in initial diffusion stages characterized by elevated noise levels. It concentrates on capturing the overarching global structures, long-term trends, and coarse patterns that are more conspicuous when noise dominates.
- **Late-Stage Diffuser ( $\epsilon_{\theta_2}$ ):** Specializes in the latter diffusion stages characterized by diminished noise levels, capturing fine-grained details, short-term patterns, and subtle variations that become more apparent as the noise subsides.

Figures 3 and 5 illustrate heatmaps of the attention weights associated with last Transformer encoder layer for each diffuser at different steps ( $T=500$ ). As depicted, the early-stage diffuser exhibits higher attention weights in the early stages ( $T=400$ ), focusing on long-term patterns, while the late-stage diffuser dominates in the later stages ( $T=100$ ), capturing short-term details. A smooth transition between the two diffusers is evident at intermediate steps (200 and 300). Furthermore, we conduct experiments to assess the potential benefits of employing more than two diffusers (Table 5). However, our findings indicate that increasing the number of diffusers to three or four doesn’t not yield improvements in model performance. Instead, it results in increased complexity and longer training and inference times. A more detailed discussion on the rationale behind using dual-stage diffusers and their effectiveness is provided in Appendix C.

To seamlessly integrate the contributions of both diffusers, a time-dependent weighting scheme is employed. This scheme dynamically adjusts the influence of each expert based on the current diffusion timestep  $t$ . The weight for the early-stage Diffuser,  $w_1$ , is defined as a function of time:  $w_1 = t/T$ , where  $T$  is the total number of diffusion steps. Conversely, the weight for the late-stage

Diffuser is  $w_2 = 1 - w_1$ . This weighting mechanism ensures a smooth and intuitive transition between the two diffusers. During the initial diffusion steps ( $t \approx T$ ) where noise levels are high,  $w_1 \approx 1$ , giving greater influence to the early-stage diffuser to effectively capture the coarse-grained features, allowing it to primarily guide the denoising process. As the diffusion process advances,  $t$  approaches 0 and the noise level decreases, the weight shifts the influence towards the late-stage diffuser with  $w_2 \approx 1$ . This transition allows the late-stage diffuser to take precedence in refining the generated samples by incorporating fine-grained details. The predicted noise is then calculated by combining the outputs of both expert diffusers, weighted according to the current timestep:

$$\epsilon_\theta(x_t, t) = w_1 \cdot \epsilon_{\theta_1}(x_t, t) + w_2 \cdot \epsilon_{\theta_2}(x_t, t) \quad (10)$$

### 3.3 DIFFUSER MODEL

Each Diffuser model employs a Transformer-based architecture tailored for multivariate time series modeling, as depicted in the right panel of Figure 2. This architecture integrates convolutional layers, transformer encoders, and advanced positional encodings to ensure efficient noise removal and high-fidelity reconstruction of temporal sequences. The noisy data  $x_t$  is initially processed by a 1D Convolutional Layer (Conv1D) that extracts localized features by learning temporal dependencies within a restricted receptive field. This local processing is essential for capturing short-range patterns while maintaining robustness to noise in the input sequence. A learnable positional encoding is then applied to preserve the temporal order and periodic characteristics of the input data. Concurrently, a sinusoidal embedding of the diffusion time step is activated using the Sigmoid Linear Unit (SiLU) and undergoes a linear transformation to provide the model with information about the prevailing noise level in the diffusion process. The transformed features from the convolutional layers, positional encodings, and diffusion time step embeddings are combined and fed into a Transformer encoder, composed of multiple stacked layers. By employing multi-head self-attention mechanisms, the Transformer can dynamically assign different weights to various parts of the sequence, capturing long-range temporal dependencies that are crucial for reconstructing coherent and realistic time series data from noisy inputs. After processing through the Transformer encoder, the features are passed through an additional Conv1D layer that maps the output back to the original feature dimension. This layer refines the output by focusing on local structures within the sequence, ensuring that the output not only aligns globally but also exhibits fine-grained detail at the local level.

### 3.4 TRAINING AND SAMPLING

Our proposed model’s training objective, as formalized in Equation 11, incorporates two loss components to ensure precise noise prediction and alignment with the underlying data distribution.

$$\mathcal{L} = \mathbb{E}_{t, x_0, \epsilon} \left[ \|\epsilon - \epsilon_\theta(x_t, t)\|^2 \right] + \lambda_{kl} D_{KL}(q(x_{t-1}|x_t, x_0) || p_\theta(x_{t-1}|x_t)) \quad (11)$$

here,  $\lambda_{kl}$  is hyperparameter balancing the contribution of the KL divergence loss.

The first term, MSE loss, quantifies the difference between  $\epsilon$ , the actual noise introduced during forward diffusion, and  $\epsilon_\theta$ , the noise predicted by the model. Based on (Kingma & Welling (2022)), the combination of  $q$  and  $p$  forms a variational autoencoder with a variational lower bound, which is a summation of KL divergences over  $t \in [0, T]$ . However, at  $t = T$ , the KL divergence  $D_{KL}(q(x_T|x_0) || p(x_T))$  becomes independent of  $\theta$  and approaches zero if the forward diffusion process effectively destroys the data distribution, such that  $q(x_T|x_0) \approx \mathcal{N}(0, I)$  (Nichol & Dhariwal (2021)). Additionally, at  $t = 0$ , the KL divergence reduces to the negative log-likelihood of  $p_\theta(x_0|x_1)$ , which we compute using the CDF. Consequently, the second term of our loss simplifies to  $\sum_{T=1}^1 D_{KL}(q(x_{t-1}|x_t, x_0) || p_\theta(x_{t-1}|x_t))$ . To compute each individual term, the Equation 4 provides an efficient method to sample from arbitrary steps of the forward diffusion process and estimate the KL divergence using the posterior distribution (Equation 6) and prior distribution (Equation 7). By randomly sampling  $t$  and calculating the expectation  $\mathbb{E}_{t, x_0, \epsilon} [D_{KL}(q(x_{t-1}|x_t, x_0) || p_\theta(x_{t-1}|x_t))]$ , we can approximate  $D_{KL}(q||p_\theta)$ . Incorporating KL loss encourages the model to generate samples whose distribution more closely approximates the true posterior distribution, thereby enhancing the accuracy of reconstructions. To empirically validate this, we present visualizations of t-SNE, KDE, and PCA plots for both the original and generated data in two experimental settings: one with both KL and MSE, and another without the KL term. The comparative results are illustrated in Figures 13 and 14 of the Appendix. Detailed training and inference procedures are outlined in Algorithms 1 and 2, respectively, in Appendix C.2.

324    **4 EXPERIMENTS**  
 325

326    **4.1 EXPERIMENTAL SETUP**  
 327

328    **Datasets.** We compiled a diverse collection of benchmark time series datasets, encompassing both  
 329    real-world and simulated data. Real-world datasets included financial data (Stocks, Stockv), me-  
 330    chanical system data (ETTh), electricity consumption data (Energy), and air quality data. Simulated  
 331    datasets included synthetic sine waves and MuJoCo physics simulations. Detailed statistics of these  
 332    datasets are provided in Table 6 and Appendix D.1.

333    **Baselines.** We conduct comparative experiments against established time series generative meth-  
 334    ods, including: KoVAE (Naiman et al. (2024b)), Diffusion-TS (Yuan & Qiao (2024)), TimeGAN  
 335    (Yoon et al. (2019a)), TimeVAE (Desai et al. (2021)), Diffwave (Kong et al. (2021)), DiffTime  
 336    (Coletta et al. (2023)), Cot-GAN (Xu et al. (2020)), T-Forcing (Sutskever et al. (2011)), which is  
 337    RNNs trained with teacher-forcing, and RCGAN (Esteban et al. (2017)). Source code links for these  
 338    methods are provided in Table 7.

339    **Evaluation Metrics.** To evaluate the quality of generated synthetic time series data, we employ a  
 340    suite of metrics, including:: Discriminative Score (Yoon et al. (2019a)). Predictive Score(Yoon et al.  
 341    (2019a)). Context-Frechet Inception Distance (Context-FID) (Jeha et al. (2022)). Correlational  
 342    Score (Ni et al. (2021)). For a more detailed discussion of these metrics, please refer to Appendix  
 343    D.3.

344    **4.2 EXPERIMENTAL RESULTS**  
 345

346    In this section, we evaluate the efficacy of our proposed model across three primary dimensions:  
 347    (1) *Representation Analysis*: We employ Kernel Density Estimation, Principal Component Analysis  
 348    (PCA), and t-Distributed Stochastic Neighbor Embedding (t-SNE) van der Maaten & Hinton (2008)  
 349    to visualize the learned representations of both the original and synthetic data. (2) *Sampling Quality*  
 350    and *Quantity*: We compare the performance of MoD against several baselines across five diverse  
 351    datasets using the four established metrics. (3) *Downstream Task Performance*: We evaluate the  
 352    performance of our model and other baselines in the contexts of long-sequence and scarce data  
 353    generation.

354    **4.2.1 COMPARISON OF GENERATED AND ORIGINAL DATA REPRESENTATIONS**  
 355

356    To evaluate the effectiveness of our proposed MoD model in capturing underlying data patterns and  
 357    generating realistic synthetic samples, we visualize the learned representations of both original and  
 358    generated data distributions across the Energy and ETTh datasets using t-SNE. Additionally, KDE  
 359    is employed to provide a more granular analysis of their distributional similarity.

360    Figure 4 demonstrates that our model exhibits a notable overlap in the KDE plot between the original  
 361    and generated data distributions, suggesting its proficiency in learning the underlying distribution.  
 362    Furthermore, the t-SNE plot reveals that the generated data from our model closely resembles the  
 363    original data, indicating its effectiveness in capturing the underlying data patterns and generating  
 364    high-quality samples. In contrast, the visualizations for Diffusion-TS and TimeGAN show a less  
 365    pronounced overlap, suggesting potential limitations in their ability to accurately represent the orig-  
 366    inal data distribution. For additional visualizations, please refer to Appendix E.

367    **4.2.2 TIME SERIES GENERATION RESULTS**  
 368

369    We evaluate the performance of MoD across a rang of data complexities with varying in dimen-  
 370    sionality. We employ four metrics to comprehensively assess data quality, with the results summa-  
 371    rized in Table 1. For each dataset, we utilize sequences of 24 time steps, aligning with common  
 372    practices in existing research (Yoon et al. (2019a)). Notably, our model consistently outperforms  
 373    baseline methods, achieving notable improvements across most metrics. On the Energy dataset,  
 374    MoD achieves a discriminative score reduction of 23%, 34%, and 60% compared to Diffusion-TS,  
 375    KoVAE, and TimeGAN, respectively. Additionally, MoD attains predictive scores close to *original*  
 376    on all datasets, indicating the high efficacy of its generated data. Furthermore, MoD demonstrates  
 377    superior preservation of temporal dependencies, with correlational score reduction of 36%, 40%,

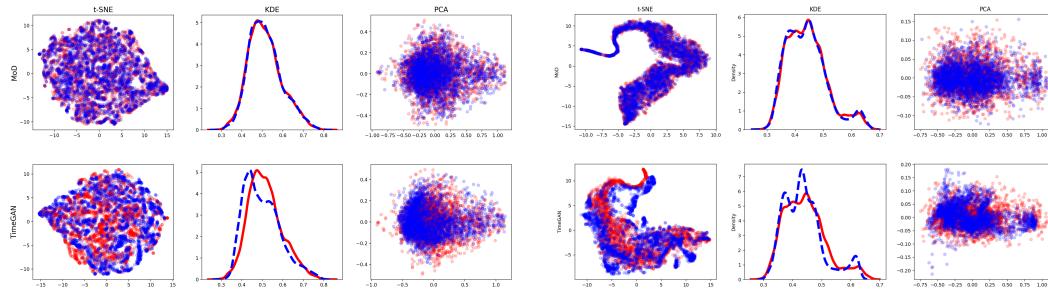

Figure 4: t-SNE, KDE, and PCA distributions visualization for the original (red) and synthetic (blue) data generated by MoD (up) and TimeGAN (down) on the ETTh (left) and Energy (right).

Table 1: Performance on multiple time series datasets. *Original* values means that predictor is trained on original data instead of synthetic data generated by various models. **Boldface** values indicate the best results, while underlined values denote the second-best performance.

and 80% to Diffusion-TS, KoVAE, and TimeGAN on MuJoCo. To complement the quantitative analysis, Figure 4 and 1 provide qualitative evaluations using t-SNE, PCA, and KDE visualizations.

The remarkable performance of MoD can be attributed to several key factors. (1) Specialization across diffusion stages through two expert diffusers, each focusing on different diffusion stages. This specialization allows each diffuser to concentrate on specific patterns associated with their respective stages. (2) Enhanced learning capacity: By specializing, MoD improves its overall learning capacity, effectively modeling both global and local patterns within the multivariate time series data. (3) Adaptive contribution of experts: The time-dependent weighting function in MoD dynamically adjusts the influence of each expert, facilitating a smooth transition between them and enhancing the model’s flexibility to capture a wide range of patterns over time. (4) Joint training: The combination of MSE loss for temporal relation preservation and KL divergence loss for improved distribution similarity enables MoD to learn a diverse set of representations.

#### 455 4.2.3 DOWNSTREAM TASKS

456  
 457 **Data Scarcity.** To evaluate the model’s performance under varying data scarcity conditions, we  
 458 conduct experiments using the experimental settings outlined in (Desai et al. (2021)). For each  
 459 dataset, we employ training sets comprising 100%, 20%, 10%, 5%, and 2% of the original data.  
 460 We then generate synthetic data for various models on four datasets. The quantity of generated data  
 461 corresponded to the percentage of original training data used to train the generators. Table 2 presents  
 462 the discriminative and predictive scores for the 20%, and 10% cases (complete results are provided  
 463 in Table 11 in Appendix E.2). Our model consistently outperforms the baselines across all scarcity  
 464 levels and datasets. Notably, the lower scores achieved by our model indicate the high quality  
 465 of the generated data even in challenging scenarios with very limited data (i.e., 2%). Moreover,  
 466 the predictive scores of our model are nearly indistinguishable from those of the original datasets  
 467 for most scarcity levels. Importantly, our model demonstrates superior performance on the high-  
 468 dimensional Energy dataset. To further visualize the quality of the generated data across different  
 469 scarcity levels, we plot t-SNE, KDE, and PCA visualizations of the generated data of our model in  
 Figures 9, 10, 11, and 12 in Appendix E.2.

470  
 471 **Long-term Generation.** To evaluate the model’s ability to generate long time series sequences  
 472 with high-quality, we conduct experiments on the Energy and ETTh datasets using sequence lengths  
 473 of 64, 128, and 256. The results are presented in Table 3 (The extended results are reported in  
 474 Table 9). Our findings demonstrate the model’s capacity to capture underlying patterns and generate  
 475 realistic samples, even when dealing with long sequences, a challenging aspect of time series data.  
 476 The model consistently achieves the best scores across most datasets with notable improvements  
 477 on ETTh dataset. For instance, our model improves the discriminative score by 84% compared to  
 478 Diffusion-TS and by 92% compared to TimeGAN. Additionally, we plot visualizations of our model  
 479 performance compared to Diffusion-TS in Figures 6 and 7 in Appendix E.1.

#### 480 4.3 ABLATION STUDY

481  
 482 To evaluate the contributions of each component within MoD, we conduct an ablation study by re-  
 483 moving individual components to assess their impact on performance. We compare the performance  
 484 of MoD against four key variants: (1) *Base Diffuser*: We replace the mixture of diffusers with a single  
 485 diffuser throughout the entire diffusion process. (2) *no Time Adaption*: We remove the time-adaptive  
 weighting function that adjusts the contribution of each diffuser based on the diffusion step. (3) *w/o*

Table 3: Long-term generation performance comparison. Extended results are provided in Table 9

Dataset	Metrics	Length	MoD	Diffusion-TS	TimeGAN	TimeVAE	Diffwave	DiffTime	Cot-GAN

Table 4: Ablation study on MoD and variants across multiple datasets.

Metric	Methods	ETTh	Energy	Sines	Stocks
Discriminative Score (Lower the Better)	MoD	0.011±.004	0.093±.006	0.007±.004	0.005±.019
	<i>Base Diffuser</i>	0.499±.000	0.149±.004	0.045±.009	0.169±.008
	<i>no Time Adaption</i>	0.012±.003	0.101±.008	0.011±.003	0.012±.001
	w/o KL	0.013±.004	0.103±.004	0.019±.008	0.045±.041
	w/o MSE	0.497±.000	0.5±.000	0.499±.000	0.5±.000
	MoD	0.017±.003	0.656±.060	0.013±.002	0.010±.003
Correlational Score (Lower the Better)	<i>Base Diffuser</i>	0.039±.002	0.875±.003	0.028±.001	0.109±.002
	<i>no Time Adaption</i>	0.019±.002	0.661±.085	0.017±.003	0.015±.004
	w/o KL	0.019±.003	0.682±.024	0.014±.002	0.012±.002
	w/o MSE	1.029±.002	6.098±.026	0.567±.001	1.25±.000

KL: This variant removes the KL divergence loss from the total loss function. (4) w/o MSE: We omit the MSE loss. The results of this ablation study are presented in Table 4.

The ablation study reveals that removing the MSE loss significantly affects the model’s performance across all datasets, demonstrating its critical role in preserving temporal dependencies. The Single Diffuser model exhibits inferior performance across all metrics, highlighting the importance of the dual-stage diffusers in enhancing the model’s ability to capture more robust and diverse representations, leading to more realistic generated samples. Removing the KL divergence loss term results in a slight decrease in performance, particularly in terms of discriminative score, indicating its role in enforcing similarity between the true and generated data distributions. By removing the time-dependent weighting function, we observe a decrease in performance across all metrics, suggesting the effectiveness of dynamically adapting the influence of each expert diffuser to capture different patterns at different stages of the diffusion process.

## 5 CONCLUSION

In this study, we have proposed MoD, a diffusion-based generative model for time series synthesis. By decomposing the diffusion process into specialized expert networks, MoD effectively captures the intricate temporal dynamics and interdependencies inherent in time series data. The segmentation of the diffusion process into two stages, coupled with the joint training regimen, ensures that the generated samples are both coherent and representative of the underlying data distribution. Our empirical evaluation demonstrates MoD’s superior performance in both representation learning and time series generation, surpassing baseline models in preserving temporal consistency, capturing data distribution, and facilitating downstream tasks. In addition to its superior performance, MoD offers a computational advantage by employing two specialized expert networks. This approach allows for the use of relatively smaller models, reducing inference time compared to a single large model. By focusing on specific aspects of the data, each expert can capture patterns more efficiently, leading to improved computational efficiency without compromising the quality of the generated samples. For a discussion of limitations and future research directions, please refer to Appendix B.

810    **A RELATED WORKS**  
811  
812  
813

814    The generation of synthetic time series data has become increasingly important due to its broad ap-  
815    plicability, with applications spanning diverse domains such as finance, healthcare, transportation  
816    and more. The unique characteristics of time series data, namely its sequential nature and temporal  
817    dependencies, necessitate specialized modeling techniques (Jarrett et al. (2021)). While real-world  
818    data is often limited or costly to obtain, the ability to synthesize realistic time series enables ad-  
819    vancements in simulation, forecasting, and decision-making (Lim et al. (2023)). To address these  
820    challenges, various deep generative models have been developed, VAEs with GANs and, more re-  
821    cently, diffusion models emerging as leading approaches in this domain. Generative models have  
822    been widely used to create high-quality data in different areas, such as images, text, and audio.  
823    However, generating time series data is more difficult because it requires capturing patterns over  
824    time and dealing with noisy or incomplete information (Liao et al. (2023)). Early methods for time  
825    series generation were mainly based on GANs, which gained prominence for their capacity to pro-  
826    duce realistic samples. GANs use two competing neural networks: a generator that creates synthetic  
827    data and a discriminator that differentiates between real and generated data (Wang et al. (2023)).  
828

829    **Generative Adversarial Networks (GANs).** Many GAN-based models have been proposed to ad-  
830    dress specific challenges in time series generation. For example, TimeGAN (Yoon et al. (2019a))  
831    incorporates both supervised and unsupervised learning techniques to capture temporal dynamics  
832    more effectively using recurrent neural networks (RNNs). RTSGAN (Pei et al. (2021)) and PSA-  
833    GAN (Jeha et al. (2022)) use self-attention mechanisms to generate high-quality long univariate time  
834    series samples, which is important for capturing long-range patterns. CotGAN (Xu et al. (2020))  
835    leverages causal optimal transport theory to generate sequences with consistent temporal patterns,  
836    while RCGAN (Esteban et al. (2017)) introduces an architectural variation by conditioning on addi-  
837    tional inputs. TTS-GAN (Li et al. (2022)) integrates a transformer encoder with GANs to generate  
838    time series data, demonstrating the utility of transformers for capturing temporal dependencies.  
839    GT-GAN (Jeon et al. (2022)) combines GANs, AEs, and differential equation models to model  
840    continuous-time flows and generate time series. Sig-WGAN (Ni et al. (2021)), which focuses on  
841    financial data, combines a continuous-time probabilistic model with the Wasserstein-1 (W1) metric  
842    to address specific challenges in generating financial time series data. Despite these advancements,  
843    GAN-based models have limitations, especially when generating long sequences. Standard archi-  
844    tectures like RNNs and CNNs struggle to capture long-term patterns, leading to poorer performance  
845    on longer time series. Additionally, GANs can suffer from the mode collapse problem, which can  
846    hinder the generation of diverse time series samples (Remlinger et al. (2021)). GANs also come  
847    with drawback during training where basic architecture  
848

849    **Variational Autoencoders (VAEs).** In addition to GANs, VAEs and normalizing flows gained at-  
850    tention for time series generation due to their probabilistic modeling capabilities. VAEs, which  
851    learn a latent representation of data by optimizing a lower bound on the data’s log-likelihood, offer  
852    a powerful framework for capturing the underlying structure of time series data. TimeVAE (Desai  
853    et al. (2021)) incorporates an interpretable temporal structure, achieving reasonable performance  
854    in generating synthetic time series. Methods based on normalizing flows, which transform com-  
855    plex distributions into simpler ones through invertible mappings, have also been explored. Fourier  
856    Flows (Alaa et al. (2021)), a notable approach, leverages a chain of spectral filters followed by an  
857    exact likelihood optimization to synthesize time series data. These models provide a flexible, inter-  
858    pretable framework for modeling time series, offering distinct advantages, such as exact likelihood  
859    estimation, over traditional methods.  
860

861    **Diffusion models**, initially developed for image, video, and text generation (Ho et al. (2020)), have  
862    recently emerged as promising alternatives to GANs for time series synthesis. Their ability to gener-  
863    ate diverse samples without suffering from mode collapse makes them particularly attractive for this  
864    task. The application of diffusion models to time series data is relatively new but has shown signif-  
865    icant potential. TimeGrad (Rasul et al. (2021)) uses an autoregressive diffusion process to forecast  
866    probabilistic multivariate time series, relying on RNNs to model temporal dependencies. DiffWave  
867    (Kong et al. (2021)) has applied CNN-based diffusion architectures to synthesize audio data, out-  
868    performing previous GAN-based approaches. Diffusion-TS (Yuan & Qiao (2024)) has integrated  
869    interpretability components, such as trend and seasonality, into the diffusion framework to enhance  
870    the modeling of time series data.  
871

Several recent studies have further refined diffusion models for time series generation. CSDI (Tashiro et al. (2021)) employs self-supervised masking, inspired by image inpainting techniques, to guide the denoising process for time series. DiffTime (Coletta et al. (2023)) introduces a variant of the diffusion model by approximating the diffusion function based on CSDI, while also incorporating guided diffusion to manage constraints like trend and fixed values without requiring retraining. Biloš et al. (2023) propose an approach for modeling time series data by treating it as a discretization of an underlying continuous function. Instead of adding independent noise to individual data points, the authors introduce the concept of adding noise to the entire function using stochastic processes. Kolloviev et al. (2023) introduce TSDiff for time series modeling using an unconditionally-trained diffusion model. This model leverages a self-guidance mechanism during inference, enabling it to adapt to various downstream tasks like forecasting, imputation, and synthetic data generation without requiring task-specific training. Yan et al. (2024) introduce D3M, a general framework for constructing generative models based on the explicit solutions of linear SDEs. D3M unifies DDPM and continuous flow models, enabling the design of generative models with high generation speed and sampling quality and shows strong performance in probabilistic time series imputation. Chen et al. (2023) explore the Schrödinger bridge problem (SBP) for generative modeling, focusing on its application in probabilistic time series imputation. They provide the first convergence analysis of the approximate iterative proportional fitting (aIPF) algorithm, used to solve SBP with approximated projections. Naiman et al. (2024b) introduce KoVAE, a VAE designed for generating both regular and irregular time series data. The key idea of KoVAE lies in its linear dynamical prior, inspired by Koopman theory, which assumes the latent dynamics of the time series can be represented by a linear map. Zhou et al. (2023b) propose LS4, a generative model for time series data that utilizes a latent space governed by a state-space ordinary differential equation (ODE) to enhance modeling capacity. It leverages a convolutional representation to accelerate computations, surpassing the need to explicitly calculate hidden states. Galib et al. (2024) introduce FIDE, a conditional diffusion model specifically designed to capture the distribution of extreme values in time series generation, where it employs a high-frequency inflation strategy in the frequency domain, ensuring the sustained emphasis on block maxima. Naiman et al. (2024a) propose ImagenTime, a framework for generative modeling of time series data by transforming sequences into images and then leveraging advanced diffusion vision models. Zhicheng et al. (2024) introduce SDformer, a two-stage method for time series generation that leverages the discrete token modeling (DTM) technique.

To enhance training and inference efficiency on resource-constrained devices, latent generative models have been explored for time series generation. These models benefit from the compact and smooth nature of the latent space, enabling more efficient computations. TimeLDM (Qian et al. (2024)) combines a VAE with a latent diffusion model. The VAE encodes time series into a smoothed and informative latent representation, while the latent diffusion model operates in this latent space to generate synthetic samples. Similarly, TimeDiT (Cao et al. (2024)) leverages the transformer architecture to capture long-range temporal dependencies and employs diffusion processes in the latent space to generate high-quality samples without imposing stringent assumptions on the target distribution. These advances demonstrate the versatility of diffusion models in capturing the complex temporal structures inherent in time series data, as they offer both robustness to noise and flexibility in handling high-dimensional data.

## B LIMITATIONS AND FUTURE WORKS

While our proposed MoD framework demonstrates effectiveness and superior performance in time series generation, it also hints at potential limitations and avenues for future exploration.

*Model Complexity and Computational Cost:* Diffusion models, in general, can be computationally expensive to train and infer, especially when applied to high-dimensional data or when a large number of diffusion steps are used. Multivariate time series data, with its complex patterns and dynamic dependencies, poses challenges for a single model to capture the full spectrum of intricacies. While the use of two specialized expert diffusers in the MoD framework improves performance, it also increases the model's complexity and computational demands compared to single-diffuser models. To address this, future research could explore techniques such as knowledge distillation to reduce the model's computational footprint without compromising accuracy.

*Conditional Diffusion:* Many real-world time series are influenced by factors beyond their intrinsic historical values. External data, such as weather conditions, economic indicators, or social media trends, can provide crucial contextual information for understanding the underlying patterns and dynamics. Incorporating such data can enhance the performance of downstream tasks like forecasting and anomaly detection. The current MoD framework does not explicitly account for external information. To address this limitation and improve performance, exploring conditional diffusion models, which can be conditioned on external data, is a promising avenue for future research.

*Irregular Time Series:* Irregular time series, characterized by non-uniformly spaced observations, present unique challenges for time series analysis. Extending the MoD framework to effectively handle irregular time series and their downstream tasks is an important direction for future research. Potential approaches include adapting the diffusion process to account for irregular time intervals or employing imputation techniques to create pseudo-regular time series.

## C MODEL DETAILS

### C.1 RATIONALE BEHIND USING DUAL-STAGE DIFFUSION

This section delves into the effectiveness of employing dual-stage diffusers within our MoD framework, providing insights into their operation during the reverse diffusion process and supporting the rationale for selecting two specialized diffusers, as opposed to adding more diffusers.

As illustrated in Figures 3 and 5, the attention weight heatmaps reveal distinct patterns for the two specialized diffusers across different diffusion stages. Early-Stage Diffuser, designed to operate effectively at higher noise levels, exhibits higher attention weights during the initial stages of reverse diffusion (notably at  $T=400$ ), where the overall structure and coarse-grained features of the data are more prominent. This influence gradually diminishes as the reverse diffusion process progresses (i.e., as  $T$  decreases from 300 to 100), reflecting the reduced significance of coarse features in later stages.

Conversely, Late-Stage Diffuser assumes a more prominent role as the noise level decreases, particularly from  $T=200$  to  $T=100$ . At these later stages, where fine-grained, high-frequency features become more apparent, Late-Stage Diffuser exerts greater attention, effectively capturing the intricate details that emerge as the data becomes less noisy. The observed transition of attention weights between Early-Stage and Late-Stage Diffusers demonstrates their complementary roles throughout the diffusion process, ensuring that both global and local aspects of the data are adequately represented.

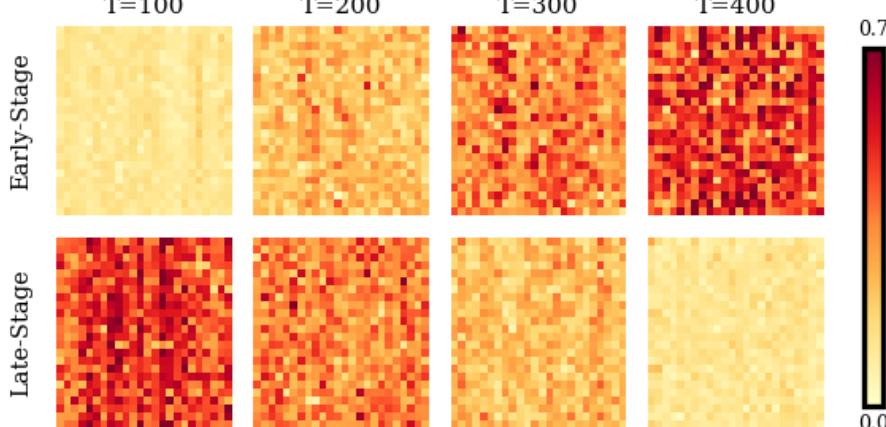

Figure 5: Attention weight heatmaps for both diffusers on Sines dataset.

980  
981  
982  
983  
984  
985  
986  
Table 5: Performance comparison of MoD with varying numbers of diffusers.

Metric	Model	ETTh	Stocks	Sines
Discriminative Score	MoD	0.009	0.008	0.006
	MoD #3	0.010	0.034	0.010
	MoD #4	0.008	0.060	0.008
Predictive Score	MoD	0.121	0.037	0.094
	MoD #3	0.121	0.037	0.093
	MoD #4	0.122	0.038	0.093
Inference Time (ms per sample)	MoD	12.13	8.34	7.93
	MoD #3	18.14	12.58	11.91
	MoD #4	24.21	16.74	16.0

987 Experimental results, summarized in Table 5, further support the efficacy of this approach. A com-  
 988 parison of MoD with three and four diffusers reveals that while MoD with two diffusers achieves  
 989 strong performance metrics across all datasets (ETTh, Stocks, Sines), adding a third or fourth dif-  
 990 fuser does not significantly improve the discriminative or predictive scores. For instance, the dis-  
 991 criminative score for ETTh is 0.009 for MoD and 0.010 for MoD #3, indicating a negligible dif-  
 992 ference. Similarly, the predictive scores across the models remain virtually unchanged. However,  
 993 increasing the number of diffusers introduces additional model complexity. As shown in Table 5,  
 994 moving from two to three or four diffusers leads to a substantial increase in inference time, rising  
 995 from 12.13 ms (MoD) to 24.21 ms (MoD #4) per sample for ETTh. This increased computational  
 996 burden is not justified by corresponding gains in predictive or discriminative performance, suggest-  
 997 ing a point of diminishing returns.

998 These results confirm that the use of two expert diffusers strikes an effective balance between model  
 999 performance and computational efficiency. This dual-stage approach is well-suited for managing  
 1000 varying noise levels during the reverse diffusion process, with one diffuser focusing on recovering  
 1001 coarse-grained features and the other on refining fine-grained details. Adding more diffusers does  
 1002 not yield tangible benefits, indicating that the time-dependent weighting scheme and expertise of  
 1003 each diffuser are well-aligned with the demands of multivariate time series data at different stages.  
 1004 This ensures that the MoD framework remains efficient while maintaining a high modeling capacity,  
 1005 capable of capturing both broad patterns and intricate details in time series data.

**D.1 DATASETS**

1024  
1025 The datasets employed in this study encompass a diverse range of temporal patterns and applications:

- 1026     1. **Sines**: A controlled benchmark dataset with customizable frequencies.  
 1027     2. **Stock and Stockv** (Yahoo and Google): High-volatility, non-stationary financial data spanning  
 1028       the 2008 financial crisis.  
 1029     3. **ETTh**: Industrial transformer data from China (2016-2018) exhibiting seasonal patterns  
 1030       and long-term trends.  
 1031     4. **MuJoCo**: Physically-constrained humanoid motion trajectories simulated using a physics  
 1032       engine.  
 1033     5. **Energy**: Electricity consumption data from Chièvres, Belgium, capturing complex interactions  
 1034       between 28 appliance circuits at 10-minute intervals over approximately 4.5 months.

1035  
 1036     The datasets used in this study are publicly available at the links provided in Table 5. Their statistical  
 1037       properties are also presented. We employ an overlapping sliding windows mechanism to arrange the  
 1038       data. This technique involves sliding a fixed-size window across the data, one step at a time. By  
 1039       allowing each data point to be part of multiple windows, this approach helps preserve the underlying  
 1040       temporal relationships within the sequence.

## D.3 EVALUATION METRICS

To comprehensively assess the quality of generated synthetic time series data, we employ a suite of metrics designed to evaluate the following key aspects:

- **Distributional Similarity**: The extent to which the synthetic data aligns with the underlying distribution of the real data.
- **Temporal Dependencies**: The preservation of temporal relationships and patterns inherent in the real data.
- **Predictive Utility**: The suitability of synthetic data as input for predictive models.

1080 We utilize the following specific metrics:  
 1081

- 1082 1. **Discriminative Score:** A classification model is trained to differentiate between real and  
 1083 synthetic data. A lower discriminative score, ideally approaching 0.5, indicates that the  
 1084 synthetic data is indistinguishable from real data by the discriminator (Yoon et al. (2019a)).  
 1085
- 1086 2. **Predictive Score:** A post-hoc sequence model is trained to forecast future values using the  
 1087 Training-on-Synthetic and Testing-on-Real (TSTR) method. A lower predictive score sug-  
 1088 gests that the synthetic data can effectively support predictive tasks (Yoon et al. (2019a)).  
 1089 This approach validates the preservation of underlying predictive relationships in the syn-  
 1090
- 1091 3. **Context-Frechet Inception Distance (Context-FID):** This metric quantifies the quality of  
 1092 synthetic data by measuring the difference in representations of time series that align with  
 1093 the local context Jeha et al. (2022). The score is computed using both mean and covariance  
 1094 statistics of the feature representations, providing a comprehensive measure of temporal  
 1095 coherence.  
 1096
- 1097 4. **Correlational Score:** Evaluates temporal dependency by calculating the absolute error  
 1098 between cross-correlation matrices of the real and synthetic data Ni et al. (2021). This  
 1099 metric is particularly effective at capturing both concurrent and lagged relationships across  
 1100 multiple variables in the time series.  
 1101

#### 1100 D.4 MODEL PARAMETERS 1101

1102 To establish default hyperparameters that perform well across various datasets, we conducted a  
 1103 limited hyperparameter tuning process. The parameters explored included batch size (32, 64, 128),  
 1104 the number of attention heads (4, 8), the number of basic dimensions (32, 64, 96, 128), and diffusion  
 1105 steps (50, 200, 500, 1000). Model training was executed on a single Nvidia 4090 GPU. Throughout  
 1106 our experiments, we employed cosine noise scheduling and optimized the network using the Adam  
 1107 optimizer with  $(\beta_1, \beta_2) = (0.9, 0.96)$ . The learning rate was initialized at 8e-4 and followed a linear  
 1108 decay schedule after 500 warmup iterations. For the KL loss, we set the  $\lambda_{kl}$  parameter to 1e-2. Table  
 1109 7 provides a comprehensive list of the hyperparameter settings used. We employed a dropout rate of  
 1110 0.1 and a residual dropout rate of 0.1. The Gaussian Error Linear Unit (GELU) activation function  
 1111 was used throughout the model. A weight decay of 0.995 and an update interval of 10 were applied  
 1112 for the Exponential Moving Average (EMA). To improve the reliability and reproducibility of our  
 1113 experiments, all metrics were averaged over 10 runs.  
 1114

1115 Table 8: Hyperparameters and training details for each dataset

## 1126 E ADDITIONAL EXPERIMENTAL RESULTS 1127

### 1128 E.1 EXTENDED RESULTS FOR LONG-TERM GENERATION 1129

1130 To further assess the model’s ability to generate long, multivariate time series data, we conducted a  
 1131 comparative analysis using t-SNE visualizations. We focused on two datasets: ETTh and Energy.  
 1132 As illustrated in Figures 6, the model’s generated data for the ETTh dataset exhibited a notable  
 1133

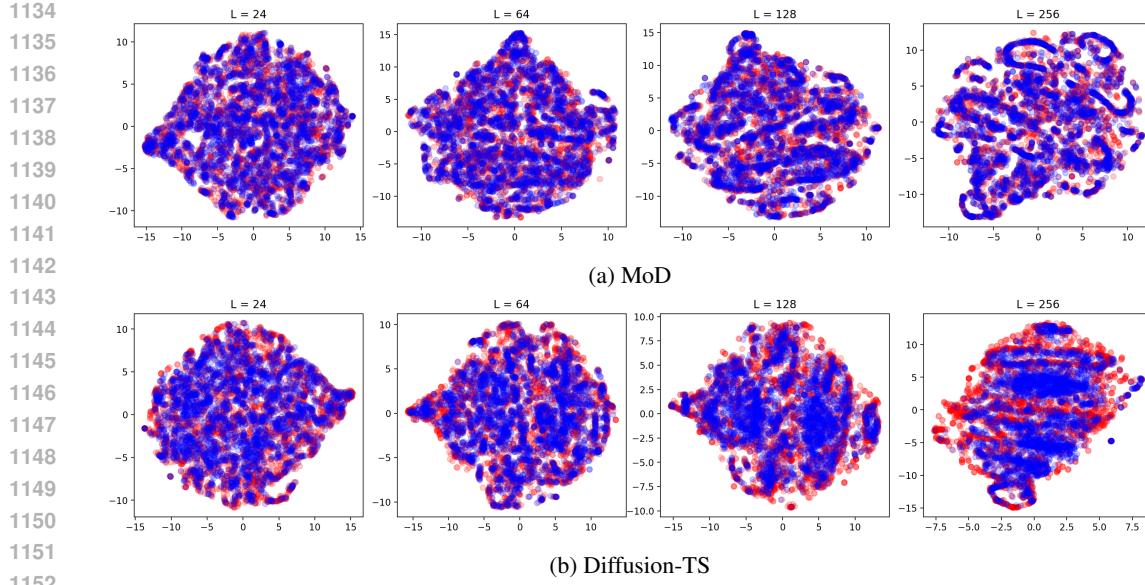

Figure 6: Effect of Sequence Length on MoD and Diffusion-TS Performance on ETTh..

improvement in similarity to the original data as sequence length increased. While the high dimensionality and large number of data points in the Energy dataset made the distinction less apparent, certain regions of the Figure 7, particularly for sequence length 64, revealed a discernible advantage of our model over the Diffusion-TS baseline.

Table 9: Performance on long-term time series generation.

## E.2 EXTENDED RESULTS FOR DATA SCARCITY

To demonstrate the model’s effectiveness in scenarios with limited data, we have included additional experimental results beyond those presented in the main paper due to space constraints. These results encompass datasets with 100%, 5%, and 2% of the original data, representing increasingly

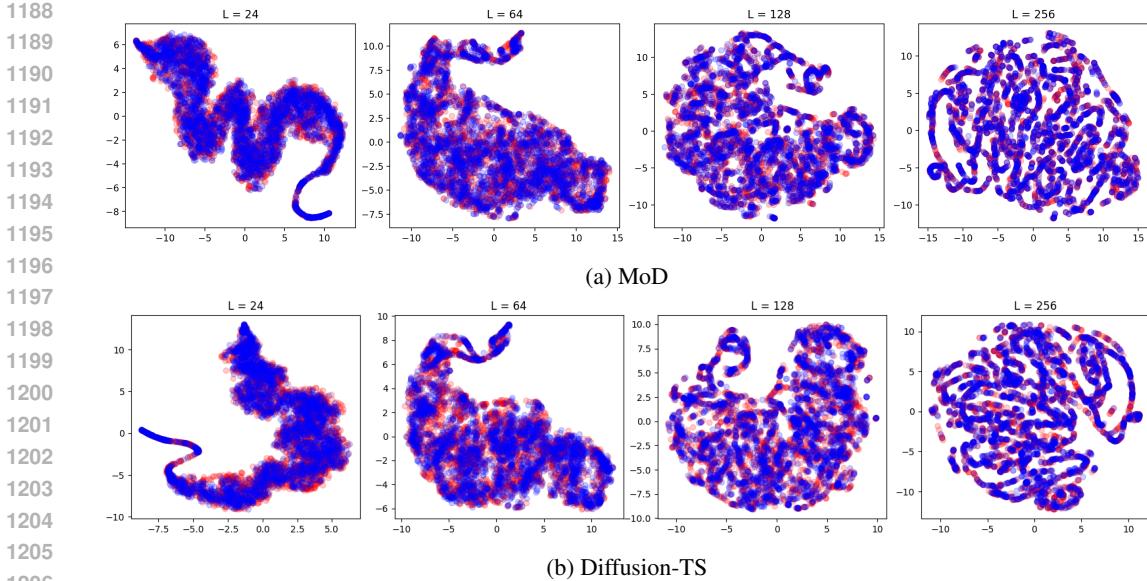

Figure 7: Effect of Sequence Length on MoD and Diffusion-TS Performance on Energy.

challenging conditions. Our findings consistently indicate that the model can generate high-quality samples even when provided with minimal data.

## F MODELING COARSE-GRAINED AND FINE-GRAINED FEATURES

To validate our hypothesis, we conducted experiments, the results of which are presented in Figure 8. Before delving into these results, we will elucidate the underlying concept.

It is well-established in image generation that the progressive introduction of noise during the forward diffusion process initially obscures fine-grained details, such as edges, textures, and small objects. These details are highly sensitive to noise perturbations. As the noise level increases, larger-scale features, including overall shapes and extensive regions, become increasingly blurred and distorted. These coarse-grained features, being less susceptible to early noise additions, remain relatively intact for a longer duration. Consequently, during the early stages of the reverse diffusion process, these dominant, coarse-grained features emerge more prominently. As the noise level diminishes, finer details gradually gain prominence.

A similar phenomenon occurs in time series data. Coarse-grained features, characterized by low-frequency, long-term trends, exhibit slower dynamics, rendering them less vulnerable to early noise corruption. Even under high noise conditions, long-term dependencies and global trends maintain a degree of robustness. Conversely, fine-grained features, comprising high-frequency, short-term fluctuations, are quickly obscured by noise, becoming more salient as the noise level decreases in the later stages of the reverse process.

To illustrate this concept, Figure 8 presents an example from the Air dataset, visualizing the diffusion process by our MoD. Time series data can be decomposed into three primary components: trends, seasonality, and residuals. Figure Z depicts the following:

- Row 1: Original time series and its decomposed components.
- Row 2: Generated data and its decomposed components at diffusion timestep T=400. The early-stage diffuser, with a weight of  $w_1=0.9$ , dominates the contribution to the generated data.
- Row 3: Generated data and its decomposed components at diffusion timestep T=100. The late-stage diffuser, with a weight of  $w_2=0.9$ , primarily contributes to the generated data.

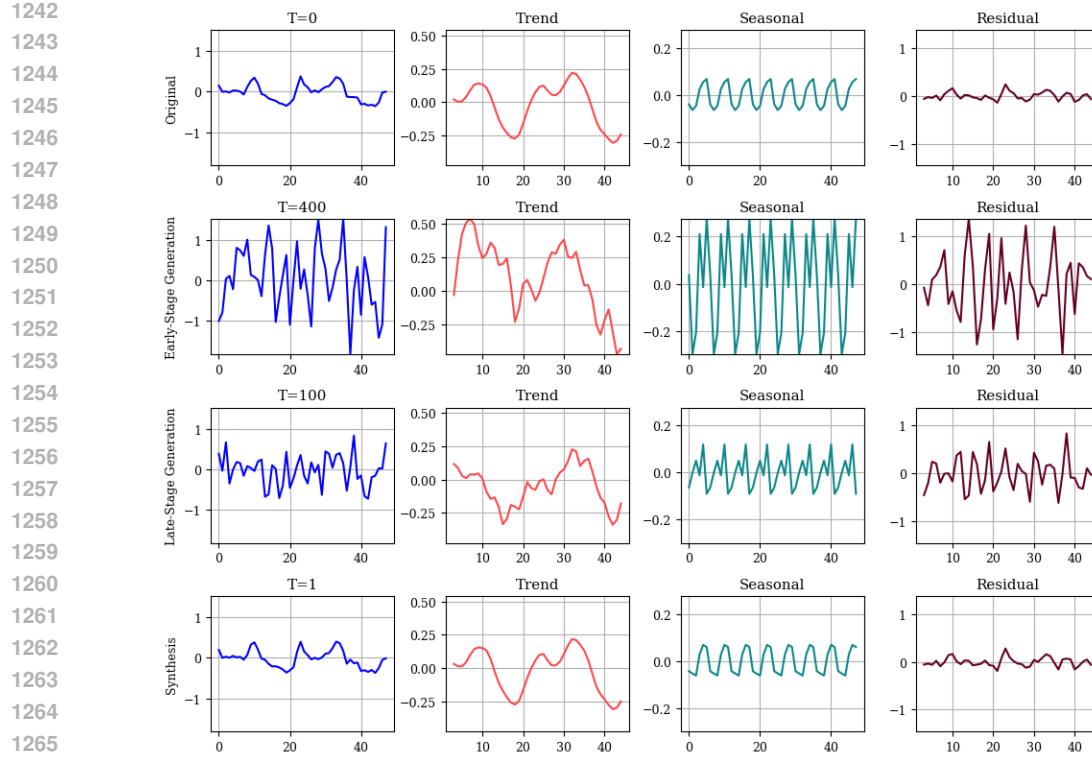

Figure 8: Visualizing the emergence of coarse-grained and fine-grained features in time series data generated by our MoD at different diffusion timesteps. The early-stage diffuser prioritizes coarse-grained features (Row 2), while the late-stage diffuser focuses on fine-grained features (Row 3). The MoD effectively balances both (Row 4).

- Row 4: Final generated data by the Model of Diffusion (MoD) at diffusion timestep T=1. Based on these visualizations, we observe the following:

*Feature-Level Analysis:* Time series data encompasses two primary feature types:

- Coarse-grained features: Low-frequency components representing long-term trends (Overall upward or downward movements in the data).
- Fine-grained features: High-frequency components representing short-term fluctuations (Rapid changes in the data that occur over short periods).

*Early-Stage Generation:* At T=400, the generated data exhibits a trend similar to the original data, characterized by two upward and one downward movement. This demonstrates the early-stage diffuser's specialization in modeling coarse-grained features, which are less susceptible to noise. Conversely, the residual component of the generated data differs significantly from the original, highlighting the difficulty of learning fine-grained representations at this stage.

*Late-Stage Generation:* At T=100, the trend of the generated data aligns more closely with the original, reflecting the refinement provided by the early-stage diffuser. The late-stage diffuser, now dominant, effectively models fine-grained features, resulting in a residual component that more closely resembles the original. *MoD Generation:* The final generated data, produced by the MoD, represents a combination of the contributions from both diffusers, effectively capturing both coarse-grained and fine-grained features.

1296 Table 10: Performance comparison of MoD and Diffusion-TS variants on Stockv and Sines datasets.  
1297

Metric	Methods	Discriminative	Predictive	# Parameters	Train (ms/epoch)	Inference (ms/sample)
Stockv	MoD	<b>0.007 ± .004</b>	<b>0.011 ± .001</b>	316.22K	56.45	14.37
	Diffusion-TS	0.187 ± .009	0.025 ± .000	203.36K	39.74	9.88
	Diffusion-TS Ensemble	0.118 ± .002	0.024 ± .000	406.81K	73.89	20.32
Sines	MoD	<b>0.005 ± .003</b>	<b>0.093 ± .000</b>	307.38K	62.73	20.08
	Diffusion-TS	0.057 ± .010	0.096 ± .000	229.75K	50.23	14.35
	Diffusion-TS Ensemble	0.038 ± .006	0.095 ± .000	459.47K	96.08	29.61

1305  
1306 G COMPLEXITY ANALYSIS  
13071308  
1309 In this section, we conduct experiments comparing our MoD model with two variants of the  
1310 Diffusion-TS model (standard and ensemble versions) across the Stockv and Sines datasets. The  
1311 comparison considered key metrics such as discriminative and predictive performance, model size  
1312 (in terms of parameters), and computational efficiency (training and inference time). The results in  
1313 Table 10 reveal the following:1314 **Performance Metrics:** (1) Stockv: MoD achieved the lowest discriminative score, representing a  
1315 96.2% improvement over Diffusion-TS and a 94.1% improvement over Diffusion-TS Ensemble. In  
1316 terms of predictive performance, MoD also outperformed the other models, showing a 56% improve-  
1317 ment over Diffusion-TS and a 54% improvement over Diffusion-TS Ensemble. (2) Sines: MoD  
1318 exhibited a discriminative score 91.2% better than Diffusion-TS and 86.8% better than Diffusion-  
1319 TS Ensemble. The predictive performance of MoD was slightly superior to both Diffusion-TS and  
1320 Diffusion-TS Ensemble, with a marginal difference of approximately 3.1% and 2.1%, respectively.1321 **Model Size:** MoD had fewer parameters compared to the Diffusion-TS Ensemble, which had a  
1322 larger model size by 28.6% on Stockv and 44.7% on Sines. The Diffusion-TS model was more  
1323 compact, requiring 35.6% fewer parameters than MoD on Stockv and 25.5% fewer parameters on  
1324 Sines. However, despite its smaller size, Diffusion-TS did not achieve the same performance as  
1325 MoD, particularly in terms of discriminative accuracy.1326 **Computational Efficiency:** (1) Train Time: MoD took 42.2% longer to train than Diffusion-TS on  
1327 Stockv, and 24.9% longer on Sines. However, the Diffusion-TS Ensemble took 30.8% longer to train  
1328 on Stockv and 47.3% longer on Sines. Compared to the Diffusion-TS Ensemble, MoD was 23.5%  
1329 more efficient on Stockv and 34.5% more efficient on Sines. (2) Inference Time: MoD required  
1330 45.3% more time for inference on Stockv and 39.7% more on Sines compared to Diffusion-TS.  
1331 However, MoD was 29.6% more efficient than the Diffusion-TS Ensemble on Stockv and 32.4%  
1332 more efficient on Sines.1333 In conclusion, our MoD model demonstrates a strong performance-to-complexity ratio across both  
1334 datasets. It consistently achieves the best discriminative and predictive performance compared to  
1335 the Diffusion-TS variants, despite having a comparable or slightly larger number of parameters.  
1336 Moreover, MoD strikes an effective balance between computational efficiency and performance. It  
1337 requires fewer resources for training and inference compared to the Diffusion-TS Ensemble, while  
1338 still maintaining a clear advantage in accuracy. Although the standard Diffusion-TS model is faster  
1339 for training and inference, MoD’s superior accuracy makes it the preferred choice when performance  
1340 is prioritized over raw speed.1341

1505 Figure 10: t-SNE, KDE, and PCA visualization of MoD performance on Stockv dataset with varying  
 1506 sizes.

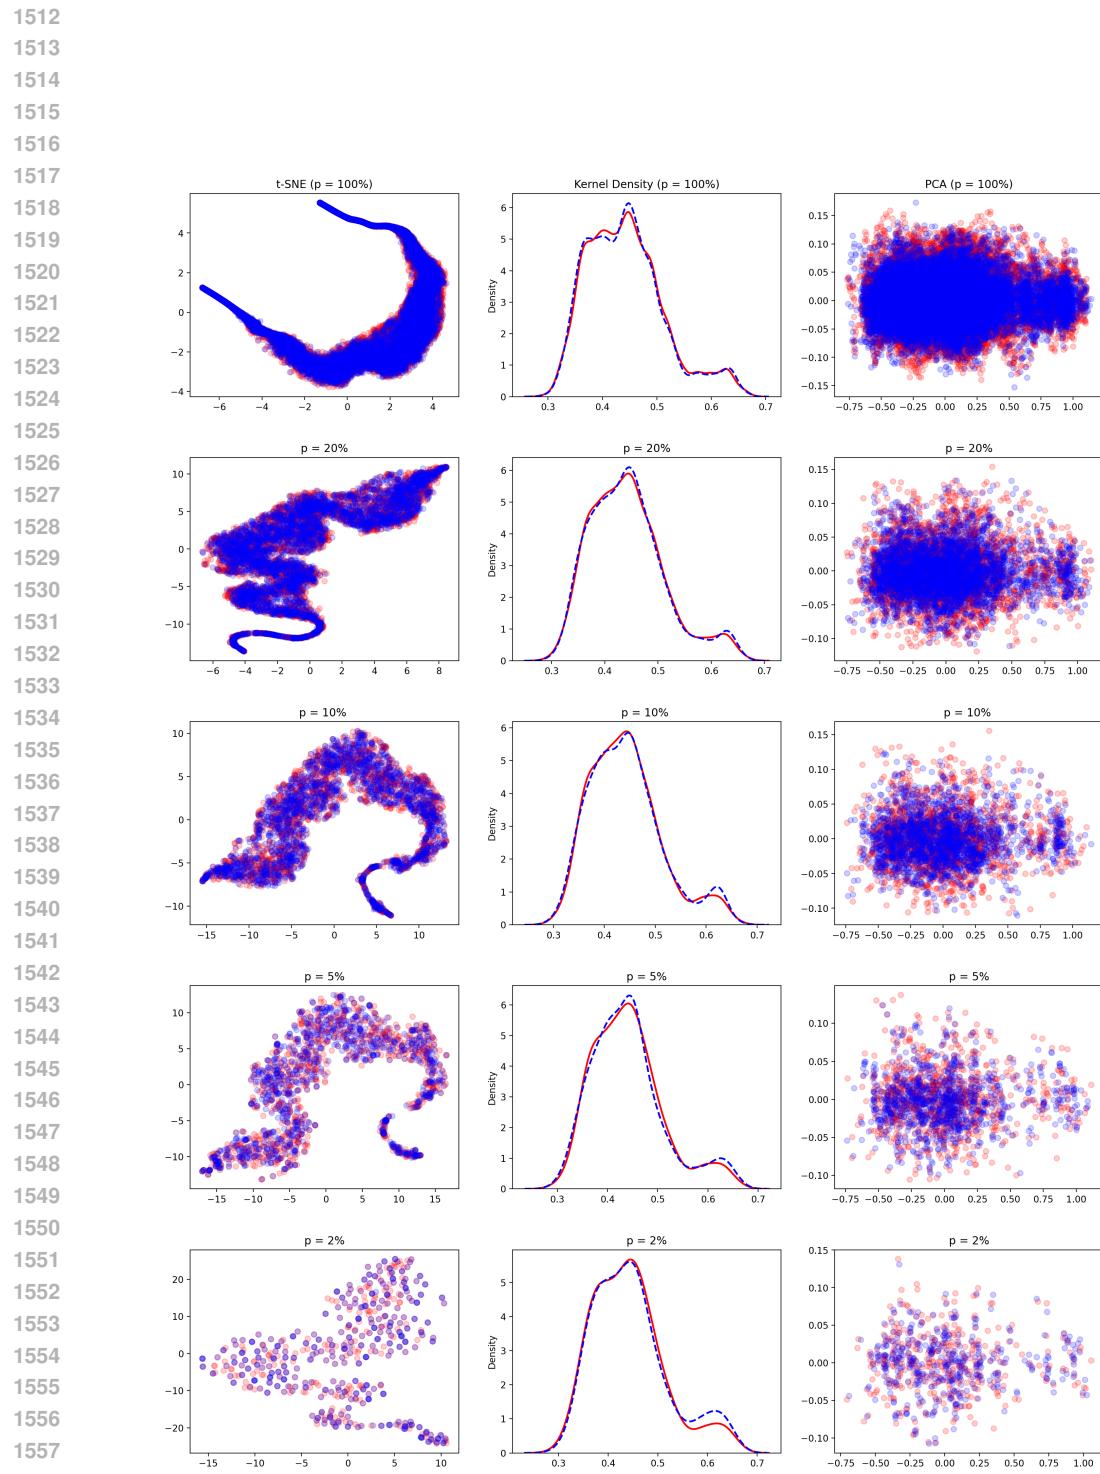

Figure 11: t-SNE, KDE, and PCA visualization of MoD performance on Energy dataset with varying sizes.

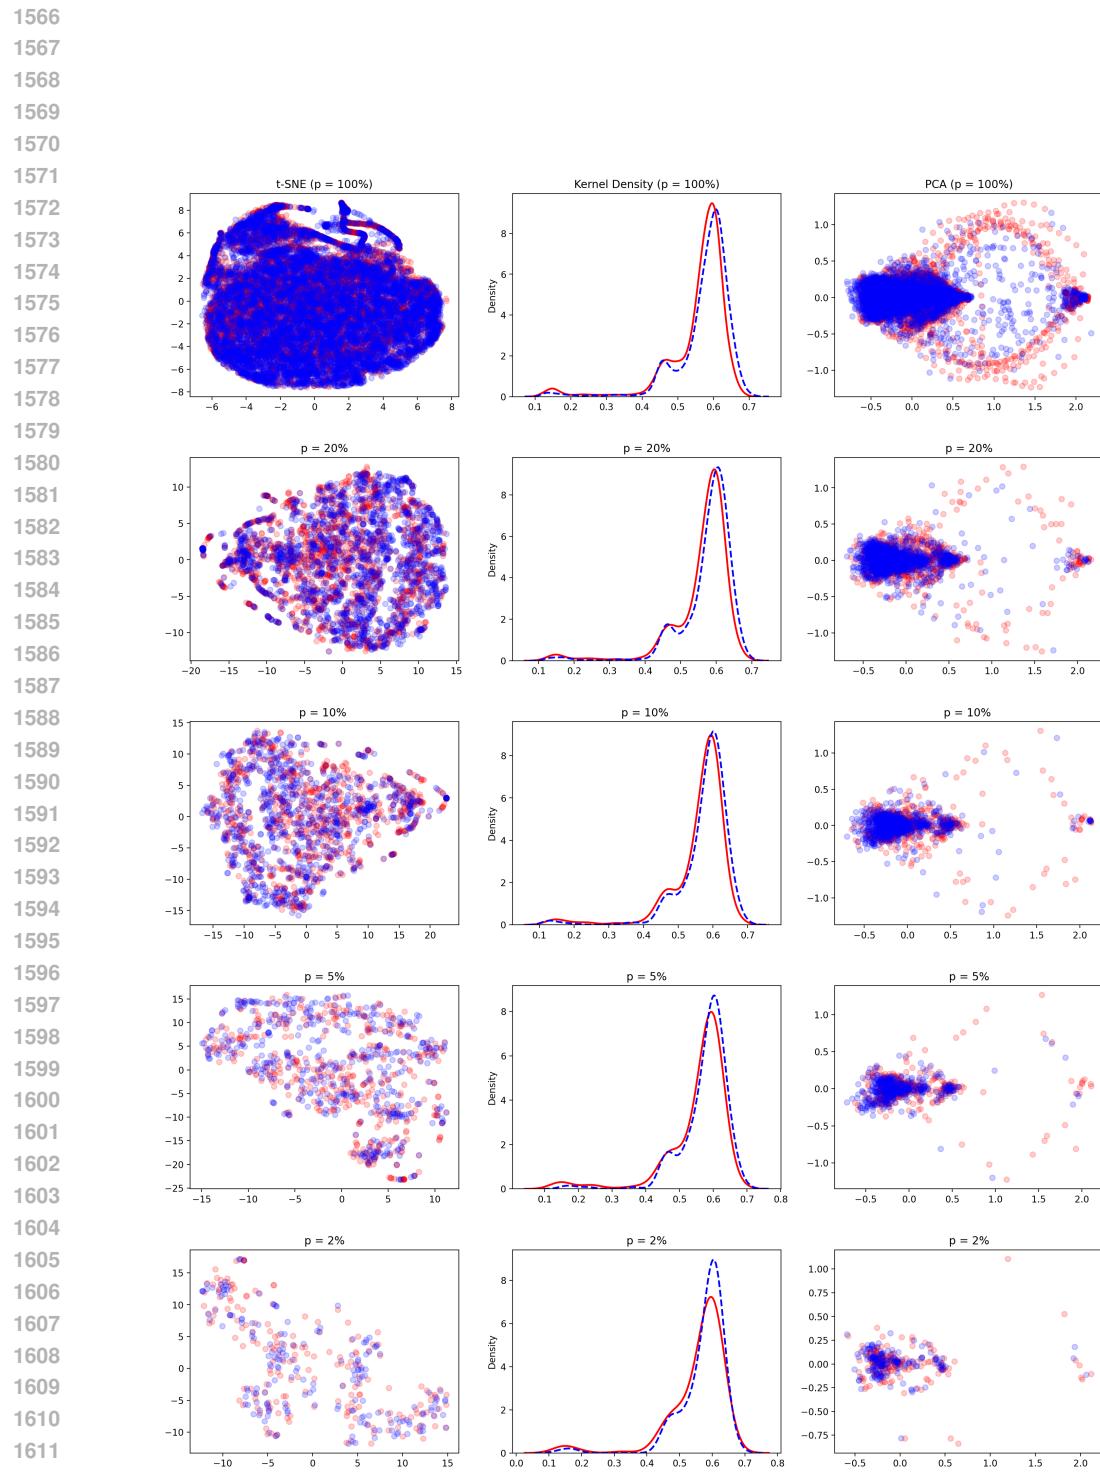

Figure 12: t-SNE, KDE, and PCA visualization of MoD performance on Air dataset with varying sizes.

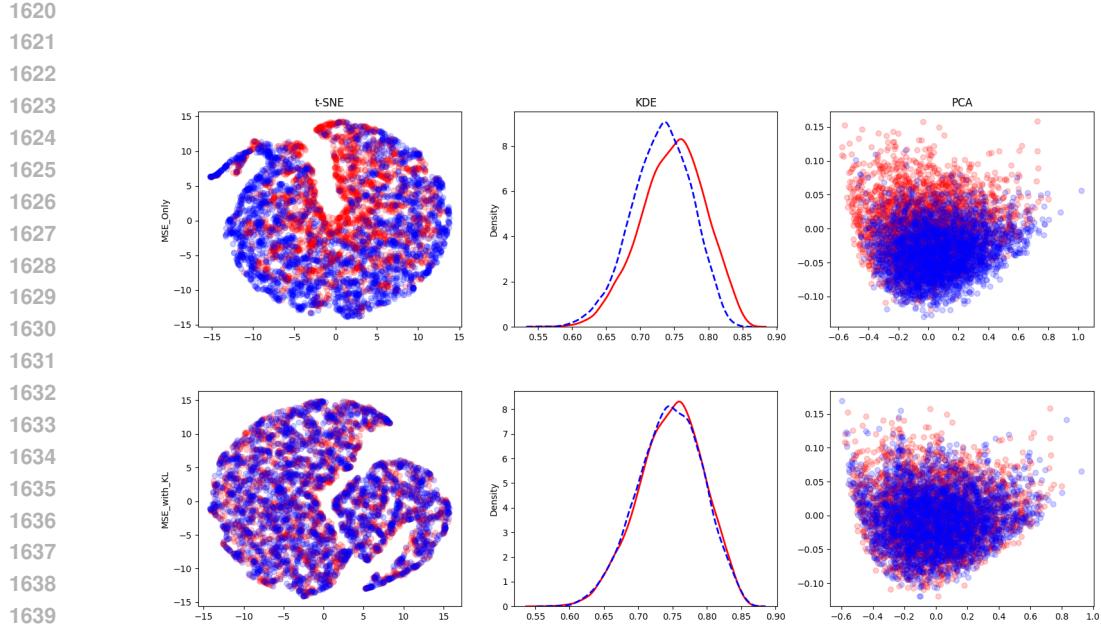

Figure 13: t-SNE, KDE, and PCA visualizations for the Sines dataset. This figure compares the generated samples from the 'MSE Only' and 'MSE with KL' models. The addition of KL divergence results in a more accurate and well-defined distribution of generated samples.

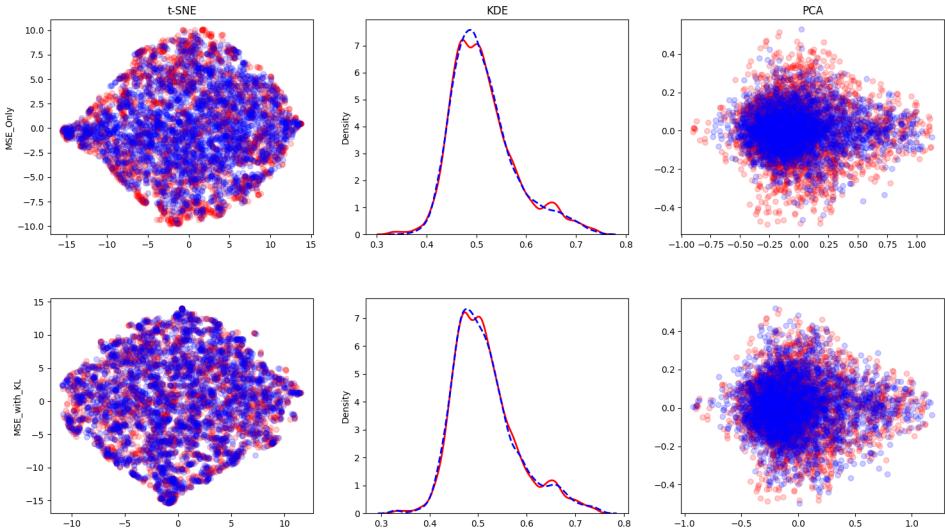

Figure 14: t-SNE, KDE, and PCA visualizations for the ETTh dataset. This figure compares the generated samples from the 'MSE Only' and 'MSE with KL' models. The 'MSE with KL' model exhibits improved performance, particularly in the KDE plot, indicating a closer alignment with the true data distribution.
